**METHOD FOR FIXATION OF TONER ON A**  
**SUPPORT OR PRINTING STOCK**

**Field of the Invention**

5           The invention concerns a method for fixation of toner on a support or printing stock, especially a sheet-like printing stock, preferably for a digital printer.

**Background of the Invention**

10           In the known method of electrostatic or electrophotographic printing, a latent photostatic image is developed by charged toner particles. These are transferred to a support or substrate that can be referred to in printing terminology as stock. The image transferred to the stock is then fixed, the toner particles being heated and melted. For melting of the toner particles, contact methods are often employed, in which the toner particles are brought into contact  
15           with corresponding devices, for example, hot rollers. A shortcoming here is that the design, maintenance and operating costs of these heating devices that operate by contact are demanding and therefore cost-intensive. The use of silicone oil as parting agent is also often required, which is supposed to prevent adherence of the melted toner to the heating device. The error rate caused by the contacting  
20           heating devices, especially in the form of paper jams, is also relatively high.

            For fixation of the toner transferred to paper, contactless heating devices and methods are also known, in which the toner particles are melted by means of heat and/or microwave radiation or with hot air, so that they adhere to the paper.

25           A known fixation device is a xenon lamp arranged above the transport path of the paper. Electromagnetic radiation can be applied to the paper, especially in the form of light, by means of a xenon lamp electrically supplied by a power supply unit, so that the toner melts and adheres to the paper surface after cooling. Xenon lamps emit radiation mostly in the visible and near infrared  
30           wavelength ranges, in which the toner has high absorption and the paper only limited absorption. This known phenomenon leads to unequal heating of the regions of the toner image having toner densities of different level. In regions of

the toner image with limited toner density, in which the toner particles are arranged more or less individually, the toner temperature is much lower than in the regions with higher toner density, because the regions with higher toner density absorb a larger fraction of the electromagnetic radiation. This different  
5 absorption behavior leads to unequal melting of the toner image in the regions with different toner density. When the toner image is exposed to such a high energy that the toner is also melted in the regions with low toner density, so-called "microblistering", often occurs in the regions of the toner image with high toner density, i.e., blister formation within the melted toner layer as a result of  
10 overheating of the toner and possibly the paper. A drawback here is that the luster of the toner image is influenced by this in an undesired manner. Partial overheating of the paper can also occur, so that it begins to curl.

With unduly low energy, it can happen that, during fixation of the toner, only an incomplete melting of the toner is achieved under some  
15 circumstances, depending on its layer thickness. Because of this, adhesion of the toner to the stock, under some circumstances, is insufficient, because the capillary effect of the stock is not adequately utilized owing to the high viscosity of the toner. In particular, problems can occur when a stock is printed on both sides in succession in two steps.

20 Because of the possible problem just outlined, despite the other drawbacks, the use of radiation alone during fixation is often dispensed with and either an additional heat source is used or the toner is heated without radiation and agglomerated into the stock regularly with a roll under the influence of pressure.

Contactless fixation, however, is desirable, in principle, to protect  
25 the printed image. A device for contactless fixation also operates largely free of wear.

#### Summary of the Invention

The underlying task of the invention is therefore to make possible  
adequate contactless fixation of toner on a stock, preferably exclusively by  
30 electromagnetic radiation, preferably also for multicolor printing on sheet-like printing stock, in which the regions of the toner image with high and low toner density have at least roughly the same melting and adhesion quality.

10023946-124704

For this purpose, it must be briefly described what the term “toner density” is to be understood to mean in connection with the present invention. In color printing, the toner image can have, for example, four toner layers of different color, the toner layers ordinarily being one each of black, yellow, magenta or cyan. The maximum density of each toner layer on the printing stock is 100%, corresponding to a density of about 1.5, measured in transmission, so that a maximum total density of the toner layers of the toner image of 400% is obtained. The density of the toner image ordinarily lies in the range from 10 to 290%. A toner layer with only 10% density is mostly formed by individual toner particles on the printing stock. The energy required to melt a toner image with a density of 10% is much higher than the energy necessary to melt a toner image with a toner density of 400%.

The posed task is solved according to the invention, in terms of the method, in that the printing stock having the toner is exposed to at least one radiation pulse or radiation flash of electromagnetic radiation and is heated for melting of the toner, and that a toner having a sharp transition from its solid to liquid state when heated is used.

In the method according to the invention, for example, a dry toner that is still quite hard at an average temperature of about 80°C or about 110°C can be used, so that it can be ground by means of conventional methods to a desired toner size of, say, 8 µm, and still does not melt even at the development temperatures, but, at higher temperatures of, say, about 110°C or about 130°C, is already suddenly fluid with low viscosity, so that it deposits on and in the printing stock, optionally with the use of capillarity and without external pressure and without contact, and adheres to it and, on cooling, then becomes hard again very rapidly and is fixed, with good surface luster, especially for lack of formed grain boundaries. The latter plays a significant role for color saturation precisely in color toners.

In conjunction with the toner according to the invention, the ratio of the value of elastic modulus  $G'$  at the reference temperature value, calculated from the initial temperature at the beginning of the glass transition of the toner plus 50°C, to the value of the elastic modulus at the initial temperature itself, can  
5 be less than  $1 \times 10E^{-5}$ , preferably even  $1 \times 10E^{-7}$ , in which E stands for a base 10 exponent.

The initial temperature at the beginning of the glass transition of the toner is preferably determined as that temperature value at which the tangent intersects the function of the elastic modulus  $G'$  versus temperature before and  
10 after the glass transition.

The transition of the toner from its solid to liquid state should preferably occur in a temperature range of about 30°K, preferably in a temperature range from about 70°C to about 130°C.

In the method according to the invention, at least one radiation  
15 pulse of electromagnetic radiation, preferably at least two radiation pulses following each other in time, is used. A second radiation pulse, for example, is triggered when the intensity of the first radiation pulse has diminished to a specific value. The time displacement between two radiation pulses is therefore the duration between triggering of the first radiation pulse and triggering of the  
20 second radiation pulse. It has been shown that, by delayed application of the second radiation pulse, the limiting value of the energy at which the toner image is overheated rises. It is therefore possible, according to the invention, for the same energy to be applied for melting of the regions of the toner image with high and low toner density without blister formation occurring in the melted toner layer.  
25 The energy of each individual radiation pulse in each case should remain below the limiting energy at which blister formation would occur in the regions of the toner image with higher toner density. The sum of the energy of all radiation pulses is high enough in each case that even regions of the toner image with low toner density are melted in the desired manner and fixed onto the printing stock  
30 because of this. With the method according to the invention at least roughly equal melting quality of the regions of the toner image with high and low toner density

can be guaranteed. It is also advantageous that adverse effects on the toner image and printing stock as a result of excess heating are avoided.

The energy densities, time spacings and/or pulse lengths in the radiation pulses can be varied with advantage and for adjustment to the  
5 corresponding circumstances.

The method according to the invention can be prescribed, in particular, for a multicolor printer. Colored toners, preferably toners of different color, are then used and fixed, one above the other and next to each other, in a toner image.

10 An absorber, especially for increased absorption of IR or UV light, can additionally be added to the toner.

As already outlined above, a toner with special melting behavior can be used according to the invention. The melting behavior of the toner can be varied or adjusted, in principle, in different ways, for example, the molecular  
15 weight distribution or the glass transition point of a toner polymer can be modified, or different mixing ratios of two or more polymers can be chosen. Other additives that influence the melting behavior in different concentrations can also be added, for example, waxes.

#### Detailed Description of the Drawings

20 Explanations of the method according to the invention as examples follow, in conjunction with two figures, from which additional inventive expedients are apparent without the invention being limited to the explained examples.

Fig. 1 shows the functional trend of the elastic modulus  $G'$  of a  
25 toner as a function of temperature for definition of the initial temperature of the glass transition of the toner; and

Fig. 2 shows the scanned functional according to Fig. 1 of different toners for comparison.

### Detailed Description of the Preferred Embodiments

The  $G'$  ratio is the ratio of elastic modulus  $G'$  at the initial temperature of the glass transition plus  $50^{\circ}\text{C}$ , to  $G'$  at the initial temperature of the glass transition. The initial temperature of the glass transition is determined,  
5 according to Fig. 1 from the intersection of the tangent to  $G'$  before and after the glass transition and lies at about  $70^{\circ}\text{C}$  in the depicted example.

The scanned functional trend of  $G'$  according to Fig. 1 is shown in Fig. 2 for four toners. The functional values of  $G'$  were determined by a rheological measurement with a Bolan rheometer, equipped with parallel plates 40  
10 mm in diameter. A temperature scan was conducted at a frequency of 1 rad/s, corresponding to 0.16 Hz between  $50^{\circ}\text{C}$  and  $200^{\circ}\text{C}$ . The strain of the measurement was chosen so that the sample exhibited no shear dilution (Newtonian behavior).

Only the two toners according to the invention exhibit a sharp  
15 transition from the solid to liquid state, with a final  $G'$  value of about  $1.00\text{E} - 02$ . A  $G'$  ratio of  $5.0\text{E} - 08$  and  $2\text{E} - 8$  results from this, with 2.5 ms pulses of the Xe flashbulb. Simultaneous fixation of 10% and 290% surfaces with an energy density of 5.1 and  $5.5 \text{ J/cm}^2$  was possible in this case.

The two other toners from the prior art show much flatter  
20 functional trends of  $G'$ , with  $G'$  ratios of  $1.9\text{E} - 03$  and  $2.2\text{E} - 05$ .

The fixation ratios of the toners according to the invention could not be implemented in these known toners. No simultaneous fixation of 10% and 290% surfaces was possible, but instead the 290% surfaces were already overheated before the 10% surfaces were fixed, because the maximum energy  
25 density for 290% surfaces was  $4.7 \text{ J/cm}^2$  and the minimum energy density necessary for 10% surfaces was  $8.3 \text{ J/cm}^2$ .

The invention has been described in detail with particular reference to certain preferred embodiments thereof, but it will be understood that variations and modifications can be effected within the spirit and scope of the invention.
